1 Introduction

Let's see what happens to the gas around stars and black holes, shall we? The primary reference for this code is (Mirocha et al., 2012, arxiv:1204.1944) – much of the text has been extracted from there.

2 Methods

2.1 The Rate Equations

In general, the chemical and thermal evolution of gas surrounding a radiation source is governed by a set of differential equations describing the number densities of all ions and the temperature of the gas. Assuming a medium consisting of hydrogen and helium only, we first solve for the abundances of each ion via

$$\frac{dn_{\text{HIII}}}{dt} = (\Gamma_{\text{HI}} + \gamma_{\text{HI}} + \beta_{\text{HI}}n_e)n_{\text{HI}} - \alpha_{\text{HIII}}n_en_{\text{HIII}} \quad (2.1)$$

$$\begin{aligned} \frac{dn_{\text{HeII}}}{dt} = & (\Gamma_{\text{HeI}} + \gamma_{\text{HeI}} + \beta_{\text{HeI}}n_e)n_{\text{HeI}} + \alpha_{\text{HeIII}}n_en_{\text{HeIII}} \\ & - (\beta_{\text{HeII}} + \alpha_{\text{HeII}} + \xi_{\text{HeII}})n_en_{\text{HeII}} \end{aligned} \quad (2.2)$$

$$\frac{dn_{\text{HeIII}}}{dt} = (\Gamma_{\text{HeII}} + \gamma_{\text{HeII}} + \beta_{\text{HeII}}n_e)n_{\text{HeII}} - \alpha_{\text{HeIII}}n_en_{\text{HeIII}}. \quad (2.3)$$

Each of these equations represents the balance between ionizations of species HI, HeI, and HeII, and recombinations of HIII, HeII, and HeIII. Associating the index i with absorbing species, $i = \text{HI}, \text{HeI}, \text{HeII}$, and the index i' with ions, $i' = \text{HIII}, \text{HeII}, \text{HeIII}$, we define Γ_i as the photo-ionization rate coefficient, γ_i as the secondary ionization rate coefficient, $\alpha_{i'}$ ($\xi_{i'}$) as the case-B (dielectric) recombination rate coefficients, β_i as the collisional ionization rate coefficients, and $n_e = n_{\text{HIII}} + n_{\text{HeII}} + 2n_{\text{HeIII}}$ as the number density of electrons.

At each time-step, we also solve for the temperature evolution, dT_k/dt , which is given by

$$\begin{aligned} \frac{3}{2} \frac{d}{dt} \left(\frac{k_B T_k n_{\text{tot}}}{\mu} \right) = & f^{\text{heat}} \sum_i n_i \mathcal{H}_i - \sum_i \zeta_i n_e n_i - \sum_{i'} \eta_{i'} n_e n_{i'} \\ & - \sum_i \psi_i n_e n_i - \omega_{\text{HeII}} n_e n_{\text{HeII}} \end{aligned} \quad (2.4)$$

where \mathcal{H}_i is the photo-electric heating rate coefficient (due to electrons previously bound to species i), ω_{HeII} is the dielectric recombination cooling coefficient, and ζ_i , $\eta_{i'}$, and ψ_i are the collisional ionization, recombination, and collisional excitation cooling coefficients, respectively. The constants in Equation 2.4 are the total number density of baryons, $n_{\text{tot}} = n_{\text{H}} + n_{\text{He}} + n_e$, the mean molecular weight, μ , Boltzmann's constant, k_B , and the fraction of secondary electron energy deposited as heat, f^{heat} . We use the formulae in Appendix B of Fukugita & Kawasaki (1994) to compute the values of α_i , β_i , ξ_i , ζ_i , $\eta_{i'}$, ψ_i , and ω_{HeII} .

2.2 Computing the Ionization and Heating Rates

The most critical aspect of propagating the radiation field in our 1D simulations is computing the ionization (Γ_i , γ_i) and heating (\mathcal{H}_i) rate coefficients accurately. In order to directly relate our results to fully 3-dimensional radiative transfer calculations we have chosen to adopt a photon-conserving (PC) algorithm nearly identical to those employed by several widely used codes, like *C²Ray* (Mellema et al., 2006), and *Enzo* (Wise & Abel, 2011). Our code is able to compute Γ_i , γ_i , and \mathcal{H}_i in a non-photon-conserving (NPC) fashion as well, to enable comparison with previous 1D work such as Thomas & Zaroubi (2008). The two formalisms are equivalent in the limit of very optically thin cells, a condition that can be met easily in 1D calculations but is rarely computationally feasible in 3D. For NPC methods, if the optical depth of an individual cell is substantial, the number of ionizations in that cell will *not* equal the number of photons absorbed for that cell, i.e. photon number will not be conserved. This problem was remedied by Abel et al. (1999), who inferred the number of photo-ionizations of species i in a cell from the radiation incident upon it and its optical depth,

$$\Delta\tau_{i,v} = n_i\sigma_{i,v}\Delta r. \quad (2.5)$$

It is most straightforward to imagine our 1D grid as a collection of concentric spherical shells, each having thickness Δr and volume $V_{\text{sh}}(r) = 4\pi[(r + \Delta r)^3 - r^3]/3$, where r is the distance between the origin and the inner interface of each shell. The ionization and heating rates can then be related to the number of absorptions in any given shell (thus preserving photon number), as

$$\Gamma_i = A_i \int_{v_i}^{\infty} I_v e^{-\tau_v} \left(1 - e^{-\Delta\tau_{i,v}}\right) \frac{dv}{hv} \quad (2.6)$$

$$\gamma_{ij} = A_j \int_{v_j}^{\infty} \left(\frac{v - v_j}{v_i}\right) I_v e^{-\tau_v} \left(1 - e^{-\Delta\tau_{j,v}}\right) \frac{dv}{hv} \quad (2.7)$$

$$\mathcal{H}_i = A_i \int_{v_i}^{\infty} (v - v_i) I_v e^{-\tau_v} \left(1 - e^{-\Delta\tau_{i,v}}\right) \frac{dv}{v}, \quad (2.8)$$

where we have defined the normalization constant $A_i \equiv L_{\text{bol}}/n_i V_{\text{sh}}(r)$, and denote the ionization threshold energy for species i as $h\nu_i$. I_v represents the SED of radiation sources, and satisfies

$$\int_v I_v dv = 1, \quad (2.9)$$

such that $A_i I_v$ is the number of photons of frequency v per atom (of species i) in a shell at radius r .

Equation 2.7 represents ionizations of species i due to fast secondary electrons from photoionizations of species j , which has number density n_j , and ionization threshold energy, $h\nu_j$. f_i^{ion} is the fraction of photo-electron energy deposited as ionizations of species i . In the remaining sections we only include the effects of secondary electrons when considering X-ray sources, which emit photons in the range $10^2 \text{eV} < E < 10^4 \text{eV}$. In this regime, the values of f^{heat} and f_i^{ion} computed via the formulae of Shull & van Steenberg (1985) are sufficiently accurate, but for radiation at lower energies where f^{heat} and f_i^{ion} have a stronger energy dependence, the lookup tables of Furlanetto & Stoeve (2010) would be more appropriate. The total secondary ionization rate for a given species, γ_i , is the sum of ionizations due to the secondary electrons from all species, $\gamma_i = f_i^{\text{ion}} \sum_j \gamma_{ij} n_j / n_i$.

The optical depth, $\tau_v = \tau_v(r)$, in the above equations is the total optical depth at frequency v due to all absorbing species, i.e.

$$\begin{aligned}\tau_v(r) &= \sum_i \int_0^r \sigma_{i,v} n_i(r') dr' \\ &= \sum_i \sigma_{i,v} N_i(r)\end{aligned}\quad (2.10)$$

where N_i is the column density of species i at distance r from the source. We calculate the bound-free absorption cross-sections using the fits of Verner et al. (1996) throughout.

The values of Γ_i , γ_i , and \mathcal{H}_i are completely predetermined for a given radiation source, and as a result, can be tabulated as a function of column density to avoid evaluating the integrals in these expressions numerically ‘on-the-fly’ as a simulation runs (e.g. Mellema et al., 2006; Thomas & Zaroubi, 2008). Isolating the frequency dependent components of Equations 2.6-2.8, we can define the integrals

$$\Phi_i(\tau_v) \equiv \int_{v_i}^{\infty} I_v e^{-\tau_v} \frac{dv}{hv} \quad (2.11)$$

$$\Psi_i(\tau_v) \equiv \int_{v_i}^{\infty} I_v e^{-\tau_v} dv, \quad (2.12)$$

allowing us to re-express the rate coefficients as

$$\Gamma_i = A_i [\Phi_i(\tau_v) - \Phi_i(\tau'_{i,v})] \quad (2.13)$$

$$\gamma_{ij} = \frac{A_j}{h v_i} \{ \Psi_j(\tau_v) - \Psi_j(\tau'_{j,v}) - h v_j [\Phi_j(\tau_v) - \Phi_j(\tau'_{j,v})] \} \quad (2.14)$$

$$\mathcal{H}_i = A_i \{ \Psi_i(\tau_v) - \Psi_i(\tau'_{i,v}) - h v_i [\Phi_i(\tau_v) - \Phi_i(\tau'_{i,v})] \}, \quad (2.15)$$

where $\tau'_{i,v} \equiv \tau_v + \Delta\tau_{i,v}$. Later references to “continuous SEDs” signify use of this technique, where the integral values Φ_i and Ψ_i are computed over a column density interval of interest a priori using a Gaussian quadrature technique, rather than on-the-fly via discrete summation.

Equations 2.13-2.15 are completely general for photon-conserving algorithms, whether the source SEDs are discrete or continuous – the only difference being for discrete SEDs, the integrals in Equations 2.11-2.12 become sums over the number of frequencies used, n_v . In practice, computing Γ_i , γ_i , and \mathcal{H}_i is more straightforward than this for sources with discrete SEDs, as we can simply count the number of ionizations caused by each individual frequency group, and convert this into the amount of excess electron kinetic energy available for further heating and ionization. When testing the accuracy of discrete solutions in later sections we employ this method, where radiation is emitted at n_v frequencies, with each frequency v_n carrying a fraction I_n of the bolometric luminosity. The photoionization and heating coefficients for each individual frequency group can then be expressed as

$$\Gamma_{i,n} = \frac{A_i I_n}{h v_n} e^{-\tau_{v_n}} (1 - e^{-\Delta\tau_{i,v_n}}) \quad (2.16)$$

$$\gamma_{ij,n} = \Gamma_{j,v_n} (v_n - v_j) / v_i \quad (2.17)$$

$$\mathcal{H}_{i,n} = \Gamma_{i,v_n} h (v_n - v_i). \quad (2.18)$$

The total rate coefficients can be found by summing each of these expressions over all frequencies, $n = 1, 2, 3 \dots n_\nu$. These equations are identical to Equations 2.13-2.15 for the discrete SED case, but are perhaps more intuitive.

2.3 Additional Complexity: Energy Dependent Secondary Electron Treatment

In the previous section (and in all of Mirocha et al. (2012)), we considered the asymptotic limit of Shull & van Steenberg (1985), in which the fractional energy deposition of secondary electrons as heat, ionization, and excitation depends only on the hydrogen ionized fraction. Ricotti et al. (2002) and Furlanetto & Stoever (2010) updated this work, providing (respectively) empirical fits and lookup tables of deposition fraction as a function of both ionized fraction and electron energy. These effects are most important at $E \lesssim 10^2$ eV.

To accommodate this model, we must redefine the quantities Φ_i and Ψ_i . We will use a tilde to denote the new quantities related to secondary ionization,

$$\tilde{\Phi}_{ij} \equiv \int_{\nu_j}^{\infty} f_{ij,(\nu-\nu_j)}^{\text{ion}} I_\nu e^{-\tau_\nu} \frac{d\nu}{h\nu} \quad (2.19)$$

$$\tilde{\Psi}_{ij} \equiv \int_{\nu_j}^{\infty} f_{ij,(\nu-\nu_j)}^{\text{ion}} I_\nu e^{-\tau_\nu} d\nu, \quad (2.20)$$

and a hat to denote the new quantities related to photo-electric heating,

$$\hat{\Phi}_i \equiv \int_{\nu_i}^{\infty} f_{(v-\nu_i)}^{\text{heat}} I_\nu e^{-\tau_\nu} \frac{d\nu}{h\nu} \quad (2.21)$$

$$\hat{\Psi}_i \equiv \int_{\nu_i}^{\infty} f_{(v-\nu_i)}^{\text{heat}} I_\nu e^{-\tau_\nu} d\nu. \quad (2.22)$$

Now, our ionization and heating coefficients read

$$\Gamma_i = A_i [\Phi_i(\tau_\nu) - \Phi_i(\tau'_{i,\nu})] \quad (2.23)$$

$$\gamma_{ij} = \frac{A_j}{h\nu_i} \left\{ \tilde{\Psi}_{ij}(\tau_\nu) - \tilde{\Psi}_{ij}(\tau'_{j,\nu}) - h\nu_j [\tilde{\Phi}_{ij}(\tau_\nu) - \tilde{\Phi}_{ij}(\tau'_{j,\nu})] \right\} \quad (2.24)$$

$$\mathcal{H}_i = A_i \left\{ \hat{\Psi}_i(\tau_\nu) - \hat{\Psi}_i(\tau'_{i,\nu}) - h\nu_i [\hat{\Phi}_i(\tau_\nu) - \hat{\Phi}_i(\tau'_{i,\nu})] \right\}. \quad (2.25)$$

Various methods for handling secondary electrons are compared for a 10^5 K blackbody source of $\dot{Q} = 5 \times 10^{48}$ ionizing photons s^{-1} in Figure 1.

2.4 Additional Complexity: Cosmological Expansion

For an expanding universe, things are slightly more complicated, as ion densities will have an additional term $\propto (1+z)^3$, and we must take into account Hubble cooling, and Compton scattering of CMB photons.

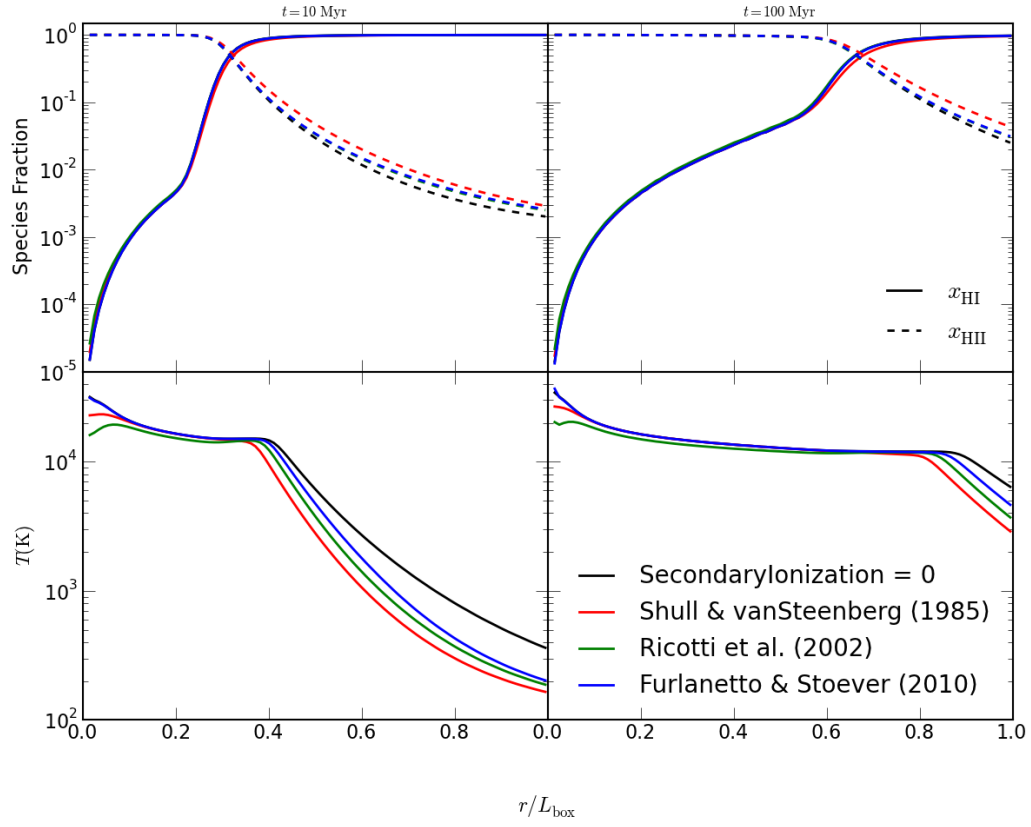

Figure 1: Comparison of different methods for secondary ionization. See §4.6 for details on setting the secondary ionization method.

Let's first account for dilution of ion densities by expansion. The number density of atoms at the cosmic mean density evolves as

$$\begin{aligned}\frac{dn}{dt} &= \frac{dn}{dz} \frac{dz}{dt} \\ &= \frac{d}{dz} (\bar{n}^0 (1+z)^3) \frac{dz}{dt} \\ &= 3\bar{n}^0 (1+z)^2 \frac{dz}{dt}.\end{aligned}\tag{2.26}$$

But, $dz/dt = H(z)(1+z)$ and $\bar{n}^0(1+z)^3 = n$, so

$$\frac{dn}{dt} = -3nH(z),\tag{2.27}$$

where we've inserted a minus sign to indicate that densities decrease with increasing time, or decreasing redshift. The right-hand side of Equation 2.27 is added to Equations 2.1-2.3 when `CosmologicalExpansion = 1`.

We must also modify the minimum and maximum column densities for our integral tables. To calculate what these should be for a simulation spanning the redshift interval (z_i, z_f) , minimum species fraction x_{\min} , and grid resolution (in proper coordinates) dx , do

$$N_{\text{HI}}^{\min} = \bar{n}_H^0 (1+z_f)^3 x_{\min} dx\tag{2.28}$$

$$N_{\text{HI}}^{\max} = \bar{n}_H^0 (1+z_i)^3 L_{\text{box}}\tag{2.29}$$

2.5 Spectrum Normalization

For convenience, we generally work with the normalized SED I_ν , such that

$$L_\nu = L_{\text{bol}} I_\nu,\tag{2.30}$$

and

$$\dot{Q}_\nu = L_\nu / h\nu.\tag{2.31}$$

However, in §7, we will discuss how `rt1d` can be used to verify choices of discrete SEDs – when `DiscreteSpectrum = 1`, we must be careful about how we normalize a spectrum.

There are two primary ways we can go about normalizing a discrete spectrum consisting of n_ν frequency bins.

The first way is to manually supply the location of each bin (in eV) and the fraction of the bolometric luminosity allocated to that bin via the parameters `DiscreteSpectrumSED` and `DiscreteSpectrumRelLum`. In Mirocha et al. (2012), we denote these quantities as $h\nu_n$ and I_n , respectively, where $n = 1, 2, \dots, n_\nu$, and do *not* require the bolometric luminosity to remain conserved. That is, we allow

$$\sum_n I_n \neq 1.\tag{2.32}$$

This is because very high energy photons (depending on the spectrum) may not be absorbed at all over the column density regime or volume of interest. It is important to note that even if $\sum_n I_n = 1$ exactly, the photon emissivity of a source constructed in this way will *not* be conserved.

For example, when we simulate a 10^5 K blackbody source emitting 5×10^{48} ionizing photons per second (as in RT06 problem #2), the `RadiationSource` class figures out the bolometric luminosity (show equations here for reference), and assigns a fraction I_n of that to bin n . In doing this,

$$L_{\text{bol}} \sum_n I_n / h\nu_n \neq 5 \times 10^{48} \text{ s}^{-1}. \quad (2.33)$$

The second approach we can use is that used in previous work such as Aubert & Teyssier (2008), which requires us to define bandpasses, each defined by an average photon energy and effective bound-free absorption cross-section. The details will be discussed in §7, but for now it is enough to know that the ionizing photon luminosity *will* be preserved with this method, assuming that the bandpasses span the full emission interval of the radiation source of interest, and the bolometric luminosity will *not* be preserved. That is,

$$\sum_n \dot{Q}_n h\nu_n \neq L_{\text{bol}}. \quad (2.34)$$

2.6 Time-stepping Techniques

2.7 Parallelism

3 Classes

In order of appearance in `RT1D.py`.

3.1 InitializeGrid

Initialize the temperature and ion densities for each cell in the grid.

3.2 InitializeIntegralTables

If `IntegralTabulation = 1` (necessary when `DiscreteSpectrum = 0`), tabulates the quantities Φ_i and Ψ_i . If `MultiSpecies = 1`, tabulation occurs for hydrogen and helium ions, and if `SecondaryIonization ≥ 2`, also tabulate $\tilde{\Phi}_i$, $\tilde{\Psi}_i$, $\hat{\Phi}_i$, and $\hat{\Psi}_i$, adding an additional dimension for x_{HII} .

3.3 RadiationSource

Initialize the radiation source. Most importantly the `Spectrum` function, which returns the fraction of the bolometric luminosity emitted at energy E (only argument).

3.4 Radiate

Calls `EvolvePhotons` routines, which loop over grid, call solver, and update ion densities and the temperature in each cell.

3.5 SolveRateEquations

ODE solver.

3.6 Interpolate

Performs linear, bi-linear, tri-linear, and eventually quad-linear interpolation on integral tables to extract ionization and heating coefficients as a function of column density.

3.7 WriteData

Write out data to HDF5. Would be easy to add support for ASCII write-out.

4 Parameters

4.1 Problem Types

These were added for convenience in January, 2011. If you want to make changes to these test problems you can, just make sure `ProblemType` is the first (uncommented) line in your parameter file. Additional parameters afterwards will be interpreted as usual.

ProblemType = 0 Single-zone.

ProblemType = 1 This will set up a standard test with known analytic solution: the propagation of an ionization front in an isothermal, hydrogen-only, static universe. The spectrum used is monochromatic at $E = 13.6$ eV, with photon luminosity $L_v = 5 \times 10^{48} \text{ s}^{-1}$. The initial density, temperature, and box size are the same as the values used in Test 1 of Wise & Abel 2010.

ProblemType = 2 This problem is almost exactly the same as `ProblemType = 1`. However, the temperature is allowed to evolve, and instead of using a monochromatic spectrum, we use a 10^5 K blackbody spectrum. Again, the initial density, temperature, box size, and energy groups are the same as the values used in Test 1 of Wise & Abel 2010.

ProblemType = 2.1 Same as `ProblemType = 2`, except we sample the continuous blackbody spectrum with the four energy groups used by Wise & Abel (2011).

ProblemType = 2.2 Same as `ProblemType = 2`, except we sample the continuous blackbody spectrum with the four energy groups used by Mirocha et al. (2012).

ProblemType = 3 Test problem # 3 from Iliev et al. (2006) – I-front trapping in a dense clump and the formation of a shadow. The setup is the same as in `ProblemType = 2`, except a 1D clump is initialized at $x = 0.76L_{\text{box}}$, overdensity $\delta = 200$, radius 0.12kpc, and temperature $T = 40\text{K}$, and the radiation field is plane-parallel.

ProblemType = 3.1 Same as `ProblemType = 3`, except we sample the continuous blackbody spectrum with the four energy groups used by Wise & Abel (2011).

4.2 Initial Conditions

`DensityProfile`

`TemperatureProfile`

`InitialHIIIFraction`

4.3 Control Parameters

ODEatol Absolute tolerance of the ODE solver. If ionized fractions are zero to this tolerance, they are reset to `MinimumSpeciesFraction`. Combination of this parameter and `ODErtol` (below) determine whether or not the ODE time-step is cut in half. (Default = 10^{-5})

ODErtol Relative tolerance of the ODE solver. Combination of this parameter and `ODEatol` determine whether or not the ODE time-step is cut in half via the formulae $|y_2 - y_1| = \text{ODEatol} + \text{ODErtol} \times y_2$. (Default = 10^{-5})

4.4 Source Parameters

`SourceType`

- 0** Monochromatic source.
- 1** Star.
- 2** PopIII star.
- 3** Black hole.
- 4** Absorbed power-law (column density given by `SpectrumAbsorbingColumn` parameter).
- 5** Multi-color disk + power-law. Relative normalization given by `SpectrumDiskFraction` parameter.

4.5 Spectrum Parameters

We keep these parameters separate from Source parameters to distinguish which parameters are allowed to vary with time, mass, luminosity, etc. This separation was useful after renovating the `RadiationSource` class in May 2012, which made it so any parameter beginning with the word ‘Spectrum’ can be a list, to allow construction of spectra consisting of an arbitrary number of components, each with uniquely specified parameters.

4.6 Physics Parameters

5 Analysis

Since our datasets are small, we can read in the entire time evolution all at once. To do this, type the following in a Python terminal:

```

import rtld.analysis as rta
import pylab as pl

ds = rta.Analyze('./pf.dat')          # load parameter file and data
pl.loglog(ds.data[10].r, ds.data[10].x_HI) # radius vs. neutral fraction

```

6 Test Problems

In this section we focus on test problems 0-3 of the Radiative Transfer Comparison Project (hereafter RT06; Iliev et al., 2006).

6.1 Test #0

Single-zone ionization, heating, and cooling.

Figure 2: Single-zone ionization, heating, and cooling RT06 #0.

6.2 Test #1

Figure 3: Convergence test for RT06 #1.

6.3 Test #2

6.4 Test #3

7 Verifying Discrete SEDs with `rt1d`

In Mirocha et al. (2012), we used `rt1d` to verify new, optimally selected discrete spectral energy distributions for sources of ultraviolet and X-ray photons. As we optimize more and more SEDs for fully 3D cosmological radiation-hydro simulations, `rt1d` remains a quick and easy tool for verifying that the SEDs we’re using are acceptable.

In the literature, discrete SEDs have been constructed using a ‘multi-group’ approach, which defines new absorption cross sections which represent spectrum-weighted averages over broad

Figure 4: RT06 #3.

Figure 5: RT06 #3.

bandpasses,

$$\tilde{\sigma}_{i,n} \equiv \int_{\nu_n}^{\nu_{n+1}} \sigma_{i,\nu} \frac{I_\nu}{h\nu} d\nu \left(\int_{\nu_n}^{\nu_{n+1}} \frac{I_\nu}{h\nu} d\nu \right)^{-1}, \quad (7.1)$$

where the interval (ν_n, ν_{n+1}) represents the bandpass bounds for discrete photon group n .

The emission energies are chosen in a similar way,

$$h\nu_n = \int_{h\nu_n}^{h\nu_{n+1}} I_\nu d\nu \left(\int_{h\nu_n}^{h\nu_{n+1}} \frac{I_\nu}{h\nu} d\nu \right)^{-1}. \quad (7.2)$$

It's worth keeping in mind that there are different ways to compute the mean photon energy in each interval. Here, we've calculated by dividing a quantity proportional to the bolometric energy output by the total number of ionizing photons. We could also compute the expectation value, median value, or even the peak of emission (e.g. for a blackbody). Equation 7.2 is most often used in the literature, so we'll stick to that.

8 Advanced Usage

In Mirocha et al. (2012)

9 Troubleshooting

If your results look horribly, horribly wrong, here are a few places where you could've gone wrong. We'll start with things that may occur with the stable version of the code.

Now, if you modify or add anything in the source code (awesome by the way!), you're far more likely to encounter troubles.

Totally Bogus Results This is will almost certainly happen at some point in the development process. But, if it happens even after you're *positive* the error was fixed, my guess is that you are using the integral tables that were generated with the previous, error-ridden version of the code. Try removing the integral tables and re-running your simulation.

10 Interactive Mode

Is it worth doing this? Would want it to look something like this:

```
import rtld
import numpy as np
pf = rtld.SetDefaultParameterValues()
r = np.linspace(3e19, 3e21, 100) # 100 grid cells between 0.01-1kpc. (optional)
data = rtld.Shine(pf, r)
```

This would make it easy to:

- Allow users to write their own rtld 'scripts.'

- Change source properties manually with time.
- Making arbitrarily structured grids.
- Very specific initial conditions.

What parameters must be set?

- ProblemType
- GridDimensions
- MultiSpecies
- LengthUnits
- InitialDensity
- SourceParameters
